Abstract

The zero-bias peak (ZBP) is understood as the definite signature of a Majorana bound state (MBS) when attached to a semi-infinite Kitaev nanowire (KNW) nearby zero temperature. However, such characteristics concerning the realization of the KNW are indeed elusive, since they constitute a profound experimental challenge. Against this scenario, we explore theoretically a QD connected to a topological KNW of finite size and show that at a non-zero temperature regime, the MBS become decoupled from each other if one tunes the system into the leaked Majorana fermion fixed point. Universal aspects of the temperature dependence of the zero-bias conductance are explored to offer additional signatures of the presence of MBS in the device. This work is a short version of our previously published work [1].

Introduction

After the advent and understanding of topological phases of matter, the proposal of topological quantum computation [2–4], which is protected against decoherence, including operations with isolated Majorana quasiparticle excitations, has triggered a remarkable theoretical and experimental synergy in the condensed matter physics community [5–8]. Among the several theoretical proposals [9–16], the one-dimensional topological Kitaev nanowire (KNW), exhibiting p-wave superconductivity feature [17] has been considered the paramount candidate to engineer isolated Majorana bound states (MBSs) at its ends.

The presence of the isolated MBSs at the edges of the KNW is inferred from tunneling spectroscopy, by analyzing the behavior of the zero-bias peak (ZBP) in the conductance profiles [18–20], which should be a hallmark of the MBS presence. This demands manufacturing long KNWs to prevent the MBSs overlapping and the consequent ZBP quenching at very low temperatures, what is considered a hard experimental challenge.

In this work, we explore the quantum dot (QD)-Kitaev nanowire (KNW) [21–26] hybrid setup sketched in Fig. 1. We address the interplay between thermal broadening and overlapped MBSs and found that effectively uncoupled edge-MBSs can pop-up at relatively large temperature ranges.

We discuss the fixed points of the model and perform a numerical renormalization group analysis [27, 28] to study the crossovers between them and the temperature dependence of the conductance. Of central importance is the leaked Majorana fixed point, that we find to occur in the vicinity of a characteristic temperature that depends solely on the KNW properties, although such a vicinity has a width that depends on the whole set of model parameters. The leakage of the Majorana fermion was first predicted theoretically in Ref. [23] and has been reported experimentally by Deng et al [20]. Further, we find rigorously the crossover temperatures and derive an analytic expression describing the universal behavior of the zero-bias conductance along the crossovers. The universal behavior reveals a more complete signature of the physical system.

Methods and Results

Assuming that the Zeeman splitting in the QD is large enough so that we can neglect the transport of spin down electrons through it, we consider the effective model with
spinless fermions \cite{21,26}, whose Hamiltonian is given by
\begin{equation}
H = \sum_{k,\alpha=U,L} \epsilon_k c_{k,\alpha}^{\dagger} c_{k,\alpha} + V \sum_{k,\alpha=U,L} \left( c_{k,\alpha}^{\dagger} d + d^\dagger c_{k,\alpha} \right) + \epsilon_d d^\dagger d + i \epsilon_m \eta_1 \eta_2 + \sqrt{2} \lambda (d^\dagger b d - b^\dagger d^\dagger),
\end{equation}
where the first term describes the conduction electrons in the upper (U) and lower (L) leads. We assume half-filled conduction bands in the particle-hole symmetric regime, with a constant density of states equal to \rho, \ -D \leq \epsilon_{k,\alpha} \leq D and Fermi energy equal to zero. The QD here has only one energy state \epsilon_d that is hybridized with the conduction states in the leads through the second term in the Hamiltonian, resulting in a linewidth \Gamma = \pi \rho V^2. We assume here symmetric coupling to the leads. The KNW is assumed to be in the topological phase with two MBSs at its ends (\eta_1 = \eta_1^\dagger), with an overlap amplitude \epsilon_m \sim e^{-L/\xi} between them, where \xi is the length of the KNW and L is the superconductor coherence length. The last term in the Hamiltonian represents the coupling between the MBS \eta_1 and the QD single state.

We consider now even and odd conduction states, \epsilon_k = (c_{k,U} + c_{k,L})/\sqrt{2} and \epsilon_{k'} = (c_{k,U} - c_{k,L})/\sqrt{2} and also the nonlocal fermionic operators \( b = (\eta_1 + i \eta_2) / \sqrt{2} \) and \( b^\dagger = (\eta_1 - i \eta_2) / \sqrt{2} \) (\(\{b,b^\dagger\} = 1\), \(\{b^\dagger,b\} = 0\)), to rewrite the model Hamiltonian as
\begin{equation}
H = \sum_k \epsilon_k \left( c_{k}^{\dagger} c_{k} + c_{k'}^{\dagger} c_{k'} \right) + \sqrt{2} V \sum_k \left( \epsilon_d c_{k}^\dagger d + d^\dagger c_{k} \right) + \epsilon_d d^\dagger d + \epsilon_m \left( b^\dagger b - \frac{1}{2} \right) - \lambda (d^\dagger b + b^\dagger d),
\end{equation}
where the odd conduction states are decoupled from the QD and the number of fermions is not conserved.

The zero-bias conductance as a function of the temperature \( T \) can be calculated from
\begin{equation}
G(T) = \frac{2e^2}{h} \pi \Gamma \left[ \frac{1}{k_B T} \sum_{n,m} |\langle n|m\rangle|^2 \right] Z \left( \epsilon_n, \epsilon_m \right) \frac{1}{\beta} \left[ \sum_{n,m} |\langle n|m\rangle|^2 \right] Z \left( \epsilon_n, \epsilon_m \right)
\end{equation}
where \( Z \) stands for the partition function for the even Hamiltonian in Eq. (2), wherein the labels \( n \) and \( m \) run over their eigenstates, whose energies are \( \epsilon_n \) and \( \epsilon_m \) respectively. Alternatively, we can rewrite Eq. (3) as
\begin{equation}
G(T) = \frac{2e^2}{h} \sqrt{\pi} \int_{-\infty}^{\infty} \text{Im} \{ G_{d,d}(\omega) \} \left( \frac{\partial f}{\partial \omega} \right) d\omega,
\end{equation}
where \( f(\omega) \) is the Fermi-Dirac function. The QD Green’s function can be promptly obtained \cite{1} from the equation of motion \cite{29} procedure.

Although the model system is quadratic and the quantum dot Green functions can be obtained analytically, we have used the Numerical Renormalization Group (NRG) method \cite{30,33} to compute the conductance as a function of the temperature \cite{27,28}, since this method allows one to follow in a natural way the crossovers between fixed points. We refer the reader to the literature for a detailed account of the method.

For a vanishing coupling \( \lambda \) between the QD and the KNW or for \( \epsilon_m \to \infty \), so that the fermionic state \( b \) becomes empty, we end up with a simple resonant level model. For non-vanishing coupling \( \lambda \) and \( \epsilon_m = 0 \) (infinite KNW), we can find \cite{1} that the zero-bias conductance through the QD approaches 0.5 \( e^2/h \) at \( \omega = 0 \) when the temperature \( T \to 0 \), whatever the values of \( \epsilon_d \) and \( \Gamma \), being a signature of the leakage of the MBS \( \eta_1 \) into the QD \cite{23}. However, any nonzero \( \epsilon_m \) makes the conductance change to its resonant level model value
\begin{equation}
G_0 = \frac{e^2}{h} \frac{4 \Gamma^2}{\epsilon_0^2 + 4 \Gamma^2} = \frac{e^2}{h} \sin^2(\delta)
\end{equation}
in the limit of zero temperature, where \( \delta \) is the phase-shift at the Fermi level. This fact prompt us to a more detailed investigation of the temperature dependence of the conductance.

\textbf{Fixed points}— Fig. [2] is clarifying. At high temperatures, when we can effectively consider both \( \lambda \) and \( \epsilon_m \) equal to zero, the conductance approaches \( G_0 \approx 0.09 \ e^2/h \) and the system is close to the free Majorana fermions fixed point. Then, as the temperature is lowered, the coupling finally emerges, leading to a crossover from a conductance equal to \( G_0 \) towards a conductance equal to 0.5 \( e^2/h \), when the system approaches the leaked Majorana fixed point. This value remains stable in a certain temperature range. At some point, however, the tiny coupling (\( \epsilon_m \)) between the Majorana fermions emerges and they become strongly coupled, yielding a new crossover ending with \( G_0 \) recovered and the system in the strongly coupled Majorana fermions. For a very long KNW (\( \epsilon_m \to 0 \)), the last crossover will be shifted...
excitations are those in a free conduction band. The system becomes the resonant level model, with the same conductance and same excitations as in the FM fixed point, but without degeneracy.

**Leaked Majorana fermion (LM) fixed point:** This corresponds to do $\lambda \to \infty$ in the model Hamiltonian. From Eq. (1), the MBS $\eta_1$ and $\eta_2$ become infinitely coupled, leading to a nonlocal fermionic level with infinite energy, that remains empty. But, we still have the MBS $\zeta_1 = (d^1 + d^2)/\sqrt{2}$ in the QD, so that the leaked Majorana fixed point is described by the following Hamiltonian:

$$H_{LM} = \sum_k \epsilon_k \hat{c}_k^\dagger \hat{c}_k + V \sum_k \left( \epsilon_k \hat{\zeta}_1 + \zeta_1 \epsilon_k \right).$$  

Essentially, the MBS has leaked from the KNW edge into the QD $[20]$. However, it is coupled to the even conduction states so that this leaking process will reach the conduction band.

With the MBS $\zeta_1$ at the QD level and $\eta_2$ at the other far edge of the KNW, we introduce a new fermionic operator, $a = (\zeta_1 + i \eta_2)/\sqrt{2}$, to rewrite $H_{LM}$ as

$$H_{LM} = \sum_k \epsilon_k \hat{c}_k^\dagger \hat{c}_k + \frac{V}{\sqrt{2}} \sum_k \left( \epsilon_k a + a^\dagger \hat{c}_k + h.c. \right).$$  

As indicated in the caption of Fig. 2 and explained in detail in Ref. [1], one half of the single-particle excitations of $H_{LM}$ are of free-conduction band type and another half of them are of $\epsilon_d = 0$ resonant level model type. Only the last set of excitations can contribute to the conductance, leading to the characteristic value of $0.5 e^2/h$ as $T \to 0$.

Now we turn to the problem of carefully identifying universal behavior in the zero-bias conductance in Fig. 3. In Fig. 3, we show the conductance for different sets of model parameters. We have used $\epsilon_d = 0$ and $\Gamma = \pi 0.005 D$, changing $\epsilon_m$ and $\lambda$. Therefore, we have conductance $G_0 = 1.0 e^2/h$ in the FM and SCM fixed points. It is clear from Fig. 3, that the crossovers occur around parameter-dependent temperatures $T_1$ (from the FM fixed point to the LM fixed point by lowering the temperature) and $T_2$ (from the LM fixed point to the SCM fixed point). We have found from the numerical results that

$$k_B T_1 = \frac{2}{\Gamma} \left( \frac{\lambda^2}{1 + \left( \epsilon_d / 2\Gamma \right)^2} \right),$$  

and

$$k_B T_2 = \frac{\Gamma}{2} \left( 1 + \left( \frac{\epsilon_d / 2\Gamma}{\epsilon_m / \lambda} \right)^2 \right) \left( \frac{\epsilon_m}{\lambda} \right)^2.$$  

One could expect that the crossover to the SCM fixed point would happen when $k_B T$ becomes of order $\epsilon_m$, since this is the energy scale of the coupling between the origin-
that means the plateau at 0.5 $e^2/h$ in the conductance will be centered at $T \sim T_2$, being well defined only if $T_2 \ll \epsilon_m/k_B$. Scaling the temperature by $T_2(T_1)$, the crossover points around $T_2(T_1)$ of the different curves in Fig. 3 collapse into the same curve as shown in Fig. 3(c). This universal curve is given by Eqs. (11) and (12) below. From Figs. 3a and 3b, we see that the temperature must be changed by at least two orders of magnitude to complete the crossover, what demands $T_1 \gg 100 T_2$ to clearly have the system in the LM fixed point. The ratio $T_1/T_2 = (k_B T_1/\epsilon_m)^2$ depends on all model parameters, what can help to tune it large enough. Naturally, the limit $T_1 \gg T_2$ can be achieved by considering very long KNWs, i.e., $\epsilon_m \rightarrow 0$, once $T_1$ is independent of $\epsilon_m$.

In general, we expect $27,28$ that the conductance between a low-temperature fixed-point where $G = G_l$ and a high-temperature fixed-point where $G = G_h$ be given by

$$G = \frac{G_l + G_h}{2} + \frac{G_l - G_h}{2} \mathcal{H}(T/T^*)$$

where $\mathcal{H}(t = T/T^*)$ is a universal function characteristic of the crossover and $T^*$ is the crossover temperature. For the model system studied here, we have found that the same universal function describes the crossover between SCM and LM fixed points and between LM and FM fixed points, being given by

$$\mathcal{H}(t) = \int_{-\infty}^{\infty} \frac{1 - u^2t^2}{1 + u^2t^2} \frac{e^u}{(e^u + 1)^2} du.$$  

**Discussion**

To make contact with a possible experimental realization of the setup in Fig. 4, we start by taking a QD energy $\epsilon_d = 0$. To fix the other model parameters, we set $T_1/T_2 = 100$ and $\Gamma/k_B T_1 = 10$ to separate the crossovers. From Eqs. (11) and (12), we have $\lambda_m = \frac{\sqrt{2}}{4}$ and $\lambda = \frac{\sqrt{2}}{3}$.

We now consider a Kitaev nanowire long enough so that $\epsilon_m = 0.001$ meV. This can be achieved experimentally $33$ for a InAs nanowire of 1500 $\eta m$. Therefore, we get $\lambda = 0.02236$ meV (very close to the reported value of 0.02353 meV $26$) and $\Gamma = 0.1$ meV. This value of $\Gamma$ is 5× larger than what is reported in Refs. $23$ and $24$ for example. However, since the barrier between the QD and the leads can be gate-tunable, $\Gamma$ can be adjusted. To ensure the spinless model validity, we must have a Zeeman splitting in the QD large compared to $\Gamma$. For a InSb nanowire, $g \mu_B B$ is of order 0.8 meV $26$ for relatively small magnetic fields ($\sim 300$ mT). Therefore, for the spin up energy $\epsilon_d = 0$, we have the spin down energy around 8Γ’s above the Fermi level, what makes negligible the contribution of the spin down channel to the conductance. For the half bandwidth $D$, we follow previous works $23,26,35$ and adopt $D = 20$ meV $\gg \Gamma$.

In Fig. 4b, we show the conductance calculated for five different values of $\epsilon_d$, with the remaining model parameters fixed with the values determined above. For $\epsilon_d = 0$ we have, by construction, $T_1/T_2 = 100$, with the system close to the LM fixed point and the conductance close to
In summary, we have determined the universal behavior of the zero-bias conductance for the simple spinless model in Eq. (1) along the crossovers connected to the LM fixed point. This enlarges the signature of the MBS in the end of the KNW and can help to reveal its presence when the LM fixed point is not fully achieved. Even with a finite KNW, it may be possible to set up the model parameters to have $T_1 \gg T_2$ and a reasonably large temperature range with conductance close to $0.5e^2/h$.

Figure 4. (a) Conductance as a function of the temperature for different values of the QD energy. Experimentally accessible values were used for the other model parameters (see main text). From top to bottom, we have $\epsilon_d = 0.0$, 0.1, 0.164, 0.244 and 0.4 meV, respectively. The continuous lines represent the calculated conductances for each $\epsilon_d$, while the points represent the universal expression of Eq. (11). For a given temperature $T$ close to $T_1$, we can accurately compute the conductance as a function of $\epsilon_d$ from Eq. (11) ($G_l = 0.5e^2/h$, $G_h = G_0(\epsilon_d)$, $T^* = T_1(\epsilon_d)$ and $\mathcal{H}(t)$ from Eq. (12)) as can be seen in Fig. 4a, where $T = 0.1$ K. Even though the plateau in the conductance at $0.5e^2/h = 0$ was not observed in Fig. 4a, the behavior in Fig. 4b follows directly from the universal description of the crossover between the LM and the FM fixed points, being another possible signature of the MBS in the system.
